## 1 Approaches to Model Adaptation

Before entering the domain of Meta-Learning, it is crucial to understand the standard paradigms for adapting a pre-trained model to a new task.

## 1.1 Standard Adaptation Strategies

When presented with a new task (e.g., a new classification problem), there is a hierarchy of adaptation strategies:

1. **Prompting:** If the model is promptable (like an LLM), simply provide instructions or examples.
2. **Linear Probing:** Use the pre-trained model as a fixed feature extractor (embedder).
  - Train a new task-specific head (e.g., linear classifier or regression layer) on top of the fixed embeddings.
  - **Advantage:** Easy to do; requires no data beyond the specific task data.
  - **Disadvantage:** Might not perform as well as full fine-tuning if the embeddings are not linearly separable for the specific task.
3. **Full Fine-Tuning:** Train all parameters (Head  $\phi_w$  and Model  $\Theta$ ).
  - Uses the pre-trained model as an initial condition.
  - **Advantage:** Typically yields higher performance.
  - **Disadvantage:** Computationally expensive; high risk of overfitting (forgetting).
4. **Parameter-Efficient Fine-Tuning (PEFT):** Approaches like LoRA (Low-Rank Adaptation) or Soft-prompting combined with a new head.

## 1.2 Practical Tips for Head Initialization

When performing a full fine-tune for a new task, the initialization of the new task-specific head is critical.

- **Bad Practice:** Do not initialize the head randomly and immediately begin full fine-tuning. Random gradients from the untrained head can degrade the pre-trained features in the early steps (sending "noise" back into the model).
- **Better Practice:** Initialize the head weights to **zero**. This ensures that initially, no gradients flow back to distort the backbone model.
- **Best Practice:** Use a subset of data to train *only* the head first (Linear Probing), then unfreeze the rest of the model for full fine-tuning.

## 2 Meta-Learning Fundamentals

**Definition:** Meta-learning is the process of making a model better at being fine-tuned for tasks. It is often described as "learning to learn."

## 2.1 Problem Setup

To perform meta-learning, we require:

1. **A distribution of tasks:** A collection of tasks from a specific family.
2. **Data Split per Task:** For each task  $i$ , we have:
  - Training set  $D_i$  (Support Set).
  - Test/Held-out set  $\tilde{D}_i$  (Query Set).
  - Loss functions  $\mathcal{L}_{train}$  and  $\mathcal{L}_{test}$ .
3. **Goal:** Find an initialization  $\Theta_0$  such that performing fine-tuning on  $D_i$  leads to low loss on  $\tilde{D}_i$  across all tasks.

## 2.2 Key Insight: The "RNN" Perspective

The process of fine-tuning via Stochastic Gradient Descent (SGD) can be viewed as the unrolling of a Recurrent Neural Network (RNN).

- The "hidden state" of this RNN is the model parameters  $\Theta$ .
- The "input" at each step is the task data  $D_i$ .
- Since RNNs are differentiable, the entire fine-tuning process is differentiable. We can back-propagate through the optimization steps.

## 3 Model-Agnostic Meta-Learning (MAML)

MAML is a general algorithm compatible with any model trained with gradient descent. The core idea is to train the initialization weights.

### 3.1 The Algorithm

The training process involves two loops: an inner loop (task adaptation) and an outer loop (meta-update).

#### 3.1.1 1. Inner Loop (Adaptation)

For a sampled task  $i$  starting at model parameters  $\Theta_0$ :

1. Compute gradient on support set  $D_i$ :  $\nabla_{\Theta} \mathcal{L}(D_i, \Theta_0)$ .
2. Update parameters (e.g., one or more gradient steps) to obtain task-specific parameters  $\Theta'_i$ :

$$\Theta'_i = \Theta_0 - \alpha \nabla_{\Theta} \mathcal{L}(D_i, \Theta_0) \quad (1)$$

where  $\alpha$  is the inner learning rate.

#### 1. 内循环: 短期特训 (Fast Stage / 快速适应)

目标: 让运动员 (模型) 用最快速度学会一个特定任务。

元素	解释
运动员	初始参数 $\theta$ 。这是运动员的***"底子"***。
任务 $T$	比如“在雪地上滑雪”，或“在泥泞跑道上赛跑”。
训练数据	任务 $T$ 的少量训练样本 ( $K$ 样本)。就像教练只给你 5 分钟热身。
动作	一步或几步梯度下降。运动员立即开始特训，调整自己的肌肉记忆。
结果	运动员 $\theta$ 变成了 $\theta'_i$ 。这是***"特训成果"***。

#### 2. 外循环: 长期进化 (Meta Stage / 慢速优化)

目标: 调整运动员的\*\*\*"先天底子" (初始  $\theta$ )，让它能更好地适应所有可能的任务\*\*。

元素	解释
评委	元学习算法。
评估数据	任务 $T$ 的少量测试样本。评委要看你特训后的成果 $\theta'_i$ 在实战中表现如何。
动作	计算元梯度 (梯度穿透)。评委不是直接奖励 $\theta'_i$ ，而是要追溯：“如果一开始的底子 $\theta$ 更好一点，这次特训的效果 $\theta'_i$ 是不是会更好？”
结果	初始底子 $\theta$ 被更新成了 $\theta_{new}$ 。

### 3.1.2 2. Outer Loop (Meta-Optimization)

Evaluate the adapted parameters  $\Theta'_i$  on the query set  $\tilde{D}_i$ :

1. Compute the test loss:  $\mathcal{L}_{test}(\tilde{D}_i, \Theta'_i)$ .
2. The objective is to minimize the sum of these test losses with respect to the *original* initialization  $\Theta_0$ :

$$\min_{\Theta_0} \sum_{i \sim p(\mathcal{T})} \mathcal{L}_{test}(\tilde{D}_i, \Theta'_i) \quad (2)$$

3. Compute meta-gradients:

$$\Theta_0 \leftarrow \Theta_0 - \beta \nabla_{\Theta_0} \sum_i \mathcal{L}_{test}(\tilde{D}_i, \Theta'_i) \quad (3)$$

where  $\beta$  is the outer learning rate.

## 3.2 Computational Challenges

Calculating  $\nabla_{\Theta_0} \mathcal{L}_{test}(\tilde{D}_i, \Theta'_i)$  requires differentiating through the inner loop update  $\Theta'_i$ . Since  $\Theta'_i$  itself depends on the gradient of  $\Theta_0$ , this involves computing **Hessian-vector products** (second-order derivatives). This is computationally expensive and memory-intensive.

## 4 Reptile: A First-Order Approximation

Reptile is a variant that avoids the explicit calculation of second-order derivatives ("backprop through backprop").

### 4.1 The Intuition

Instead of explicitly optimizing for the sensitivity of the loss to the initialization, Reptile simply moves the initialization towards the parameters obtained after fine-tuning on a task.

### 4.2 The Algorithm

1. Sample a task  $i$ .
2. Perform  $k$  steps of SGD on task  $i$  starting from  $\Theta_0$  to reach  $\Theta_{final}$  (Standard training).
3. Update the initialization  $\Theta_0$  by interpolating towards  $\Theta_{final}$ :

$$\Theta_0 \leftarrow \Theta_0 + \beta(\Theta_{final} - \Theta_0) \quad (4)$$

Here,  $(\Theta_{final} - \Theta_0)$  serves as a proxy for the meta-gradient.

## 5 Meta-Learning for Linear Probes (ANIL / MetaOptNet)

Sometimes we do not want to fine-tune the whole model at test time, but rather learn a feature extractor  $\phi$  such that a linear head  $w$  can be learned very efficiently (Linear Probing).

## 5.1 Differentiable Closed-Form Solvers

For regression tasks (and arguably classification via approximations), the optimal linear head  $w^*$  has a closed-form solution given the features  $\Phi$  and labels  $Y$ .

### 5.1.1 Ridge Regression Example

For a task with inputs  $X$  and labels  $Y$ , let  $\Phi(X)$  be the features extracted by the model. The optimal head  $w^*$  for Ridge Regression is:

$$w^* = (\Phi^T \Phi + \lambda I)^{-1} \Phi^T Y \quad (5)$$

## 5.2 Optimization Process

Since the calculation of  $w^*$  involves only differentiable matrix operations (matrix multiplication, inversion):

1. Pass support set  $X$  through model to get  $\Phi$ .
2. Compute  $w^*$  using the closed-form formula (Eq. 5).
3. Evaluate loss on query set using  $w^*$  and query features.
4. Backpropagate the query loss *through* the closed-form calculation of  $w^*$  to update the feature extractor parameters  $\Theta$ .

This allows for calculating gradients without iterative unrolling of SGD, making it highly efficient.

## 6 Catastrophic Forgetting

**Definition:** When adapting a model to a new task, it often forgets how to perform previous tasks.

### 6.1 Conceptual Analogy

Think of machine learning as blowing up a "leaky balloon."

- The data acts as the air pressure inflating the balloon (the model's capabilities).
- Weight decay and loss are leaks.
- If you stop inflating one part (Task A) to inflate another (Task B), the first part deflates. Without the pressure of the original data, the weights drift, and knowledge is lost.

### 6.2 Practical Solution

The standard solution is **Replay/Mixing**:

- During fine-tuning, mix in a small percentage (e.g., 10%) of the original pre-training data.
- If the pre-training task had distinct heads, keep them active and computing loss during fine-tuning.
- This provides a gradient signal that anchors the shared weights, preventing them from drifting too far from the generalizable representation.
